

BME464L Project (Fall 2013, Palmeri)

Respiratory Therapy Device (New)

Clinical Problem

Pompe disease is a glycogen storage disease (GSD) in pediatric and adult populations that results in significant neuromuscular deficits, including cardiac and respiratory failure. While some pharmacologic treatments are promising to improve cardiac function, respiratory failure still remains the principle source of morbidity and mortality.

Current respiratory therapy devices are crude, lack clinician control, and provide limited-to-no feedback to the patient. Patients can potentially over-train without this feedback, which can exacerbate the muscular weakness that they are trying to compensate for with their therapy.

Project Objective

Design a new inspiration and exhalation respiratory therapy device that provides therapeutic control, data recording, training safety, and patient feedback, as specified by your assigned clinician. The creation of a device with these features has broad-based application across many diseases and conditions.
